Program: Computer Science

Advisor: Prof. Dr. Paulo A. Vechiatto de Miranda.

This document is presented for the author’s PhD degree.

São Paulo, September 2019
Efficient Hierarchical Layered Graph Approach for Multi-Region Segmentation

This thesis version contains corrections and changes suggested by the Committee in Charge during the defense of the original version of the work, held at 03/15/2019. A copy of the original and correction versions are available at the Institute of Mathematics and Statistics of the University of São Paulo.

Committee in Charge:

- Prof. Dr. Paulo André Vechiatto de Miranda - IME-USP
- Prof. Dr. Fábio Augusto Menocci Cappabianco - UNIFESP
- Prof. Dr. Silvio Jamil Ferzoli Guimarães - PUC-MG
- Prof. Dr. Thiago Vallin Spina - CNPEM
- Prof. Dr. Ronaldo Fumio Hashimoto - IME-USP
I am profoundly grateful to my family, my mother Ilsa, my father Jose and brothers Roy and Edwin, who are always in my mind and my heart. To my husband Jorge for his extensive and endless support and love, and to my lovely children: Christopher and my unborn baby Fabrizio who are my main motivation in everything.

My deepest appreciation and sincere thanks to my supervisor Professor Dr. Paulo André Vechiatto de Miranda for his strong support, expertise, guidance and persistent help, greatly conducting me throughout my PhD.

I would like to thank Prof. Dr. Krzysztof Chris Ciesielski from Department of Mathematics, West Virginia University, USA, who collaborated in the formalism of our proposed method.

My gratitude to Prof. Dr. Fábio A. M. Cappabianco, Prof. Dr. Silvio J. F. Guimarães, Prof. Dr. Thiago V. Spina, and Prof. Dr. Ronaldo F. Hashimoto, who were involved in the examination committee, for their comments during the thesis defense.

I would like to thank as well my friends from the lab, specially to Leandro and Jihan. Also, a special thank to Professor Dr. Roberto Hirata Jr., who always supported me and helped me in different academic and personal circumstances.

I would like to thank CNPq [308985/2015-0, 486083/2013-6, 486988/2013-9, FINEP 1266/13], FAPESP [2011/50761-2, 2016/21591-5], CAPES, and NAP eScience - PRP - USP for funding. This research is also part of the FAPESP Thematic Research Project [proc. 2014/12236-1] and part of the INCT of the Future Internet for Smart Cities funded by CNPq [proc. 465446/2014-0], CAPES [proc. 88887.136422/2017-00], and FAPESP [proc. 2014/50937-1].
Image segmentation refers to the process of partitioning an image into meaningful regions of interest (objects) by assigning distinct labels to their composing pixels. Images are usually composed of multiple objects with distinctive features, thus requiring distinct high-level priors for their appropriate modeling. In order to obtain a good segmentation result, the segmentation method must attend all the individual priors of each object, as well as capture their inclusion/exclusion relations. However, many existing classical approaches do not include any form of structural information together with different high-level priors for each object into a single energy optimization. Consequently, they may be inappropriate in this context. We propose a novel efficient seed-based method for the multiple object segmentation of images based on graphs, named Hierarchical Layered Oriented Image Foresting Transform (HLOIFT). It uses a tree of the relations between the image objects, being each object represented by a node. Each tree node may contain different individual high-level priors and defines a weighted digraph, named as layer. The layer graphs are then integrated into a hierarchical graph, considering the hierarchical relations of inclusion and exclusion. A single energy optimization is performed in the hierarchical layered weighted digraph leading to globally optimal results satisfying all the high-level priors. The experimental evaluations of HLOIFT and its extensions, on medical, natural and synthetic images, indicate promising results comparable to the state-of-the-art methods, but with lower computational complexity. Compared to hierarchical segmentation by the min-cut/max-flow algorithm, our approach is less restrictive, leading to globally optimal results in more general scenarios, and has a better running time.

**Keywords:** Multiple object segmentation; hierarchical image segmentation; image segmentation based on graphs; interactive segmentation; superpixels; medical image segmentation.
Leon, Leissi M. C. Abordagem Eficiente baseada em Grafo Hierárquico em Camadas para a Segmentação de Múltiplas Regiões. 78 f. Tese (Doutorado) - Instituto de Matemática e Estatística, Universidade de São Paulo, São Paulo, 2019.

A segmentação de imagem refere-se ao processo de particionar uma imagem em regiões significativas de interesse (objetos), atribuindo rótulos distintos aos seus pixels de composição. As imagens geralmente são compostas de vários objetos com características distintas, exigindo, assim, restrições de alto nível distintas para a sua modelagem apropriada. Para obter um bom resultado de segmentação, o método de segmentação deve atender a todas as restrições individuais de cada objeto, bem como capturar suas relações de inclusão / exclusão. No entanto, muitas abordagens clássicas existentes não incluem nenhuma forma de informação estrutural, juntamente com diferentes restrições de alto nível para cada objeto em uma única otimização de energia. Consequentemente, elas podem ser inapropriadas nesse contexto. Estamos propondo um novo método eficiente baseado em sementes para a segmentação de múltiplos objetos em imagens baseado em grafos, chamado Hierarchical Layered Oriented Image Foresting Transform (HLOIFT). Ele usa uma árvore das relações entre os objetos de imagem, sendo cada objeto representado por um nó. Cada nó da árvore pode conter diferentes restrições individuais de alto nível, que são usadas para definir um dígrafo ponderado, nomeado como camada. Os grafos das camadas são então integrados em um grafo hierárquico, considerando as relações hierárquicas de inclusão e exclusão. Uma otimização de energia única é realizada no dígrafo hierárquico em camadas, levando a resultados globalmente ótimos, satisfazendo todas as restrições de alto nível. As avaliações experimentais do HLOIFT e de suas extensões, em imagens médicas, naturais e sintéticas, indicam resultados promissores comparáveis aos métodos do estado-da-arte, mas com menor complexidade computacional. Comparada à segmentação hierárquica pelo algoritmo min-cut/max-flow, nossa abordagem é menos restrictiva, levando a resultados globalmente ótimos em cenários mais gerais e com melhor tempo de execução.
Palavras-chave: Segmentação de múltiplos objetos; segmentação hierárquica de imagens; segmentação de imagens baseada em grafos; segmentação interativa; superpixels; segmentação de imagens médicas.

1.1 Examples of image segmentation. (a) A binary segmentation of a horse from its background and (b) a multi-object segmentation of birds from their background. ................................................................. 1

1.2 Example of interactive image segmentation by IFT. (a) An input CT image of the liver with the initial segmentation result from the user selected seeds (purple stroke for background and yellow stroke for the object). (b) An improved segmentation result for the liver is obtained by adding more seeds. ....... 3

1.3 The results of segmentations on two natural images by Deep Extreme Cut and by a particular case of HLOIFT, in single object setting and with no high-level priors. (a,c) The results by Deep Extreme Cut with 4 clicks. (b,d) The results by HLOIFT with arc-weight estimation from (de Miranda et al., 2010) using only 3 and 2 clicks, respectively. Notice, that Deep Extreme Cut has poor boundary adherence in the pepper segmentation while in the flower segmentation it invades the surrounding green area of the leaves. .......... 4

1.4 Example of multi-object segmentation by IFT. (a) A given input CT image with its initial segmentation result from the user selected seeds, where purple stroke stands for background, while yellow, cyan and red colors stand for the liver, aorta and the abdominal region respectively. (b) By adding more seeds an improved result is obtained, but it still has many imperfections. .......... 6

2.1 Example of segmentation by OIFT. (a) A given input image with the user selected seeds, where the red color stands for background, while yellow stands for the object (central bone). (b) A segmentation result by OIFT favoring transitions from bright to dark pixels; and (c) a segmentation by OIFT favoring transitions from dark to bright pixels. ......................... 14

2.2 Star Convexity: (a) A star-convex object. (b) Violation of the star-convexity prior, where p is a point of the given object and c is the star center considered. 14
2.3 (a) Input image with seeds selected by the user. (b) Segmentation result by OIFT without the Geodesic Star Convexity. (c) Result by OIFT with Geodesic Star Convexity, favoring a segmentation with a more regular shape. 

2.4 Example of segmentation using geometric interactions. Given an input image (a) involving three objects: liver \((O_1)\), aorta \((O_2)\) and abdominal region \((O_3)\) with selected seeds in yellow, blue and red colors respectively. We have \(O_1\) excluded from \(O_2\), and both are included in \(O_3\). Then, the segmentation result by our proposed method is shown in (b).

3.1 Overview of our framework. Given the input parameters, a hierarchical weighted digraph of layers (digraphs) is constructed using the *inclusion* (solid line) and *exclusion* (dashed line) hierarchical constraints between objects, and a graph-cut measure is optimized by our algorithm. Finally, we have a labeled image as output. (Compare to Figure 4.13. Notice, that only three seeds are used.)

3.2 Illustration of inter-layer arc construction, involving two objects \(O_i\) and \(O_j\), for the inclusion case (\(O_j\) is the parent of \(O_i\), i.e., \(h(i) = j\)), where \(\omega(s, t) = -\infty\) and \(\omega(t, s) = \infty\) for \(\lambda(s) = i\) and \(\lambda(t) = j\).

3.3 Illustration of inter-layer arc construction, involving two objects \(O_i\) and \(O_j\), for the exclusion case (\(O_i\) and \(O_j\) are siblings), where \(\omega(s, t) = -\infty\) for all inter-layer arcs \((s, t)\).

3.4 Illustration of the inter-layer arc construction, involving three objects \(O_i\), \(O_j\) and \(O_k\), where \(O_k\) is the parent of two sibling objects, \(O_i\) and \(O_j\), i.e. \(h(i) = h(j) = k\).

4.1 Example of two object segmentation by HLOIFT, where \(O_2\) is parent of \(O_1\). Each object has different high-level priors –db: polarity from dark to bright pixels, bd: polarity from bright to dark pixels and g: geodesic star convexity prior.

4.2 Example showing how changing the \(\rho\) value from 0 to 2 can improve the archaeological fragment segmentation by HLOIFT, avoiding a result with touching objects.

4.3 Knee segmentation composed of three objects in a CT image, including the patella in blue. (a-b) Result by IFT where the \(O_1\) is mixing bright and dark boundaries. (c-d) An improved result for the central bone is obtained by HLOIFT with boundary polarity from bright to dark pixels, requiring fewer seeds.

4.4 Talus \((O_1)\) and calcaneus \((O_2)\) segmentation. The two objects are siblings. For HLOIFT, we used \(\rho = 0\), the geodesic star convexity and boundary polarity \((\alpha = -0.75)\).
4.5 Liver ($O_1$), aorta ($O_2$) and abdomen ($O_3$) segmentation on a CT slice image. For HLOIFT, we used $\rho = 0$, $h(1) = h(2) = 3$ and the geodesic star convexity shape prior with the bright to dark boundary polarity ($\alpha = 0.75$).

33

4.6 An axial cross section of a thoracic-abdominal CT image segmentation. We consider the following objects: right lung ($O_1$), liver ($O_2$), heart ($O_3$), left lung ($O_4$), aorta ($O_5$) and the thoracic-abdominal region ($O_6$). HLOIFT obtained a result similar to the given ground-truth (manual segmentation), in contrast to the output by IFT.

34

4.7 Flower segmentation in two objects, the central part in cyan and the petals in yellow, using the inclusion relation. (a) The input image. (b) Result by the min-cut/max-flow algorithm in layered graphs. (c) Result by HLOIFT.

35

4.8 (a) Seeds obtained by eroding the ground truth of each object/background with 48 pixels radius. (b) Multi-object result by IFT. (c) The result by hierarchical layered graph cut (HLGC) mistakenly assigns the aorta as part of the liver. (d) A better result is obtained by HLOIFT.

37

4.9 The mean curves of Dice accuracy for different methods.

38

4.10 (a) Given the input image with six regions and seeds for $O_1$ (in yellow), $O_2$ (in blue) and background (in red), we obtain the result for $O_1$ and $O_2$ included in $O_3$, where $O_1$ has boundary polarity from bright to dark and $O_2$ from dark to bright. In (b) a slice view is shown and in (c) the 3D renderings of the objects.

39

4.11 (a) Given the input image with six regions and seeds for $O_1$ (in yellow), $O_2$ (in blue) and background (in red), we obtain the result for $O_1$ and $O_2$ included in $O_3$, where $O_1$ and $O_2$ have boundary polarity from dark to bright, and $O_3$ has the opposite orientation from bright to dark. In (b) a slice view is shown and in (c) the 3D renderings of the objects.

4.2 Time in ms for the different methods and image resolutions. . . . . . . . . 41
Image segmentation is the task of partitioning an input image into regions of interest by assigning distinct labels to their composing pixels. Hence, all of the pixels sharing a same label in the image form an object, see Figure 1.1. The image segmentation involving the partitioning of image into a foreground and a background (representing every other part of the image that is not the foreground) is known as binary segmentation, see Figure 1.1(a). It can only be used to segment one object at a time. However, in practice, we often need to segment multiple objects from a single image simultaneously, where each label corresponds to a different object in the image, as shown in Figure 1.1(b).

Figure 1.1: Examples of image segmentation. (a) A binary segmentation of a horse from its background and (b) a multi-object segmentation of birds from their background.

The image segmentation task is not only one of the most fundamental and challenging problems in image processing and computer vision, but also has impact in different research areas such as Ecology, Medicine, Neurology and Artificial Intelligence (Gordon et al., 2016; Toennies, 2012; Visser et al., 2016). For example, in medical imaging, image segmentation can be used to isolate the objects corresponding to different organs in Magnetic Resonance...
Images (MRI), helping to analyze their forms, volumes and textures for the diagnostic of pathologies (Jackowski e Goshtasby, 2005). However, to achieve an ideal segmentation in medical imaging, we usually have critical obstacles to face such as noise, inhomogeneity effects, low contrast and complexity of objects. The incorporation of prior knowledge into the segmentation algorithm is useful for more accurate results.

The segmentation task can fall into one of three categories: manual segmentation process, automatic segmentation and interactive segmentation. The manual segmentation process can be a tedious work for humans, being time-consuming and prone to errors due to the large amount of data. The automatic segmentation algorithms usually model the objects of interest, through a training process on a large amount of manually labeled data. On the other hand, an interactive segmentation method combines computers and humans’ expertise. Seed-based methods can be employed for interactive segmentation, where a set of “seed” pixels (or scribbles), specifying the regions of interest and their respective labels, is indicated by the user. This partial labeling is then propagated to the other pixels, allowing the user to evaluate the result and edit the final segmentation by adding more seeds if it is not satisfactory, until no further modification is needed.

Our work belongs to the seed-based class of segmentation methods, which requires as input some seeds/scribbles representing the localization of the regions of interest as constraints. We mainly focus on the interactive graph-based segmentation approach for multi-object segmentation. In the context of interactive segmentation, our method has the following pipeline: 1) A user/method provides an initial input; 2) the algorithm produces its resulting segmentation; 3) the user may provide further constraints based on the previous results, and go back to step 2. This process repeats until the results are satisfactory.

In this chapter, we briefly start presenting some state-of-the-art methods and discuss how the usage of prior information from the target objects may improve the multi-object segmentation results. Then we highlight our proposal and give the supporting reasons for choosing Oriented Image Foresting Transform (OIFT) (Miranda e Mansilla, 2014) for the energy optimization. Finally we provide a summary of our main contributions and briefly outline the organization of this thesis.

### 1.1 Interactive graph-based segmentation

Currently, interactive graph-based methods are commonly used in image segmentation tasks, where the image is modeled as a connected graph. Graph-based image segmentation is popular, because graphs can naturally represent image parts and their relationships (Golodetz et al., 2017). Here, the image segmentation task can be interpreted as a graph partition problem subject to hard constraints, such as seed pixels selected in the image domain for the foreground regions and background (anywhere outside the foreground). Examples of interactive graph-based methods are watershed from markers (Cousty et al.,
1.1. INTERACTIVE GRAPH-BASED SEGMENTATION

Random walks (Grady, 2006), fuzzy connectedness (Ciesielski et al., 2007), graph cuts (GC) (Boykov e Funka-Lea, 2006), grow cut (Li et al., 2012), minimum barrier distance (Ciesielski et al., 2014) and image foresting transform (IFT) (Ciesielski et al., 2018; Falcão et al., 2004). Figure 1.2 shows an example of interactive image segmentation by IFT (Ciesielski et al., 2018; Falcão et al., 2004) for the single object segmentation of the liver. (a) The user provides seeds as hard constraints representing foreground and background; and then an initial graph partition is obtained by energy optimization. (b) The initial segmentation can be further edited by adding new foreground and/or background seeds in order to improve the results.

![Figure 1.2: Example of interactive image segmentation by IFT. (a) An input CT image of the liver with the initial segmentation result from the user selected seeds (purple stroke for background and yellow stroke for the object). (b) An improved segmentation result for the liver is obtained by adding more seeds.](image_url)

Some methods, including the min-cut/max-flow algorithm, can provide global optimal solutions according to a graph-cut measure in graphs and can be described in a unified manner according to a common framework, which we refer to as, Generalized GC (GGC) (Ciesielski et al., 2012). Oriented Image Foresting Transform (OIFT) (Falcão et al., 1998; Miranda e Mansilla, 2014) and Oriented Relative Fuzzy Connectedness (ORFC) (Bejar e Miranda, 2015) are GGC methods designed for directed weighted graphs, which have low computational complexity compared to the min-cut/max-flow algorithm (Boykov e Funka-Lea, 2006).

Image segmentation can also be interpreted as a classification problem at the pixel level. Not surprisingly, machine learning-based methods are among the most prominent solutions to the segmentation problem, especially after the advent of deep learning techniques (He et al., 2016). In this context, a state-of-the-art method in grabcut-style (Rother et al., 2004) for interactive segmentation with minimal user involvement is Deep Extreme Cut (Maninis et al., 2018). It considers extreme points (left-most, right-most, top and bottom pixels at the object boundary) as 4 clicks for each object, and the Convolutional Neural Network (CNN) produces the segmented masks. This type of user input is
usually a good choice for single-shot algorithms, since from the 4 indicated points we can infer object’s bounding box, and consequently, all points outside the box belong to background. At first glance, this seems to be better than other types of user inputs, since arbitrary points do not allow us to draw any further conclusions. However, it is not possible in general to get a segmentation result with ground truth quality using only a 4 points selection, since considerable residual errors all around the boundary are quite common (Figures 1.3a and c). Moreover, user input in grabcut-style is usually not appropriate to perform further corrections, such that a different type of corrective action is usually employed in approaches like GrabCut ([Rother et al., 2004](#)), resulting in a less user-friendly interface due to the multiple types of input. On the other hand, deep learning techniques require a lot of annotated data for training the network and for many applications the availability of gold standard is quite limited.

![Figure 1.3: The results of segmentations on two natural images by Deep Extreme Cut and by a particular case of HLOIFT, in single object setting and with no high-level priors.](image)

(a) (b)

(c) (d)

In this work, we focus on the interpretation of the image segmentation as a graph partition problem subject to hard constraints, given by seed pixels selected in the image
domain, such that a refined segmentation can be obtained with an arbitrary level of precision, leading to a high-quality ground-truth data. The intended methods in graphs are very flexible. Besides being easily extensible for multidimensional images, they allow several customizations, such as the usage of different image elements as its nodes (e.g., superpixels (Leon e de Miranda, 2019)), the learning of graph weights by means of machine learning techniques (de Miranda et al., 2010) (see Figures 1.3b and d), or even the incorporation of learning by deep learning techniques (Wolf et al., 2017; Wolf et al., 2019). For the sake of simplicity and space constraints, here we focus only on the base form of the proposed method at the pixel level, without the use of training images, and discuss the use of high-level priors that can be easily set based on the application knowledge.

1.2 Multi-object segmentation

Most successful segmentation methods usually incorporate some image prior information. In the context of multiple object segmentation, each object may present its own distinctive features, requiring different high-level priors. Priors or global object properties refer to some prior knowledge used to guide the segmentation process. For example, priors such as connectedness (Mansilla et al., 2016; Vicente et al., 2008), shape constraints (Gulshan et al., 2010; Isack et al., 2016; Mansilla e Miranda, 2013b; Veksler, 2008), convexity prior (Gorelick et al., 2017), and boundary polarity (Miranda e Mansilla, 2014; Singaraju et al., 2008) are potentially useful high-level priors for object segmentation, allowing the customization of the segmentation to a given target object.

Also, it is advantageous for the segmentation method to explore the structural interaction/relations between the different objects in the image, whenever it is possible. In order to obtain a good segmentation result, the segmentation method must attend all individual object priors and capture the contextual or structural relations between them. However, many existing methods do not include any form of structural information or only include high-level priors for single object segmentation (Gulshan et al., 2010; Mansilla et al., 2016; Miranda e Mansilla, 2014; Vicente et al., 2008). Consequently, they may be inappropriate in the context of multiple objects.

Most of the methods for multi-object segmentation that include structural information are based on graph-cut optimization and are performed by a min-cut/max-flow algorithm (Delong e Boykov, 2009; Delong et al., 2012; Ulén et al., 2013). These methods usually use priors, based on inclusion or exclusion interactions between objects. However, their globally optimal results are restricted only to some particular cases. For example, they cannot represent the inclusion of a pair of adjacent objects in a third object. Also they usually have a high computational cost.

The methods based in Layered Optimal Graph Image Segmentation for Multiple Objects and Surfaces (LOGISMOS) (Oguz e Sonka, 2014; Yin et al., 2010) require an approximated
pre-segmentation whenever the objects present complex shapes. Note that the fast segmentation obtained by our proposed method could also be used as a starting point for LOGISMOS.

In the context of segmentation by the Image Foresting Transform (IFT) framework, in order to incorporate structural information among objects, the methods usually employ Fuzzy Object Models (FOMs) (Miranda et al., 2009; Mohammadianrasanani, 2013; Rittner et al., 2014; Sun et al., 2014; Tong et al., 2013; Udupa et al., 2013, 2014, 2011, 2012). However, these approaches are based on separate IFT executions per object, that do not incorporate structural information and the high-level priors of all objects into a single energy optimization, limiting their potential.

In Figure 1.4, we have an example of multi-object segmentation by IFT in a Computed Tomography (CT) image composed of three objects representing the liver, aorta and the abdominal region, which are shown in yellow, cyan and red color, respectively. Initially, IFT gets unsatisfactory results (Figure 1.4a). By adding more seeds the segmentation result is improved, however, it still presents many errors (Figure 1.4b). Our hypothesis is that by the usage of high-level priors, such as the geodesic star convexity and the boundary polarity from bright to dark pixels for the three regions, superior segmentation results can be obtained. Unfortunately, the existing IFT based approaches for multi-object segmentation do not support the incorporation of these constraints related to global object properties.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{example.png}
\caption{Example of multi-object segmentation by IFT. (a) A given input CT image with its initial segmentation result from the user selected seeds, where purple stroke stands for background, while yellow, cyan and red colors stand for the liver, aorta and the abdominal region respectively. (b) By adding more seeds an improved result is obtained, but it still has many imperfections.}
\end{figure}

1.3 Proposal

In this work, we circumvent the aforementioned problems, by proposing a hierarchical layered graph-based approach for the multiple object segmentation problem, named as Hierarchical Layered OIFT (HLOIFT), using a single energy optimization. A graph used in HLOIFT for a segmentation of $m$ objects is formed with $m$ layers, copies of image scene
1.4. OUTLINE

graph, each associated with an object. The hierarchy considers inclusion and exclusion constraints between objects as in Delong e Boykov (2009), but each object in the image can also have its own set of high-level priors. Further, we formulate the integration of individual object constraints and structural priors from layers, within a single energy optimization, overcoming the mentioned limitations from previous works and conserving the low computational cost of OIFT.

1.3.1 Why optimization by OIFT?

The proposed method in this work uses a modified OIFT algorithm (Miranda e Mansilla, 2014) as its main optimization algorithm, as justified for the following reasons:

- The OIFT algorithm has a good balance between accuracy and robustness in practice (Tavares et al., 2017).
- It achieves globally optimal results according to a graph-cut measure (Miranda e Mansilla, 2014).
- It has low computational cost (linear for most applications).
- It is flexible, allowing the incorporation of different high-level priors, such as shape constraints (de Moraes Braz et al., 2019) and boundary polarity, into a single energy for object segmentation.

1.3.2 Contributions

Therefore, our main contributions are as follows.

- **Theoretical**: We propose a new seed-based method for multi-object segmentation allowing high-level priors for image objects and the hierarchical constraints between them.
- **Generality**: Our approach is less restrictive than most methods in use and leads to globally optimal results in more general scenarios compared to Delong e Boykov (2009).
- **Complexity**: Our method has lower computational complexity as compared to methods based on the min-cut/max-flow algorithm.

1.4 Outline

Our work is organized as follows: In Chapter 2, we introduce some required definitions and review the OIFT method with some commonly used priors. Our new algorithm HLOIFT, is described in Chapter 3 and the proof of its correctness is given in Appendix A. In Chapter 4,
we present the experimental results, including the 3D case and the usage of superpixels for the nodes. The usage of superpixels allows us to reduce the running time of HLOIFT while conserving its accuracy. There is also some quantitative experimental evaluation of HLOIFT, comparing it against IFT and hierarchical segmentation by the min-cut/max-flow algorithm. Finally, the remaining conclusions are stated in Chapter 5.
This chapter provides the theoretical foundations of our proposed method. Here, we describe the image and digraph definitions, the related methods and algorithms, and the high-level priors to be used in HLOIFT. The details provided here are necessary for fully understanding our proposal and the results presented in subsequent chapters.

2.1 Definitions

2.1.1 Image

An (2-dimensional) image is a pair \((\mathcal{I}, I)\), where \(\mathcal{I}\) is a finite set of pixels identified with the 2-tuples of integers (i.e., \(\mathcal{I} \subset \mathbb{Z}^2\)) and \(I\) is a mapping that assigns to each pixel \(t \in \mathcal{I}\) its intensity \(I(t)\), that is, either a real number (in case of monochromatic image) or an appropriate vector in \(\mathbb{R}^k\).

2.1.2 Image as digraph

An image can be interpreted as a weighted digraph (i.e., directed graph) \(G = (\mathcal{N}, \mathcal{A}, \omega)\) whose nodes (vertices) are the pixels in the image domain \(\mathcal{N} = \mathcal{I}\), arcs/edges listed in \(\mathcal{A}\) are the ordered pairs \((s, t) \in \mathcal{I}^2\) of pixels (usually, in 2D images, identified with either 4- or 8-neighborhoods), and the weight map \(\omega\) associates to each arc \((s, t) \in \mathcal{A}\) a value \(\omega(s, t) \in [-\infty, \infty]\) (usually defined as \(\omega(s, t) = \|I(t) - I(s)\|\)).\(^1\) We use the notations \(t \in \mathcal{A}(s)\) and \((s, t) \in \mathcal{A}\) to indicate that \(t\) is adjacent to \(s\).

2.1.3 Symmetric digraph

A digraph \(G\) is symmetric if for all \((s, t) \in \mathcal{A}\), the pair \((t, s)\) is also an arc of \(G\), that is, \((t, s) \in \mathcal{A}\). All digraphs we consider in this work are symmetric. Notice, that in the symmetric weighted digraphs we may still have \(\omega(s, t) \neq \omega(t, s)\).

\(^1\)The symbol \(\|\cdot\|\) denotes the standard Euclidean norm in \(\mathbb{R}^k\).
2.1.4 Image segmentation

In binary segmentation, whose goal is to separate an object $O_1$ from its background $O_0 = \mathcal{I} \setminus O_1$, we consider two non-empty disjoint seed sets $S_0, S_1 \subset \mathcal{I}$ indicating, respectively, $O_0$ and $O_1$ (i.e., aiming for $O_1 \supset S_1$ and $O_0 \supset S_0$). So, we assume that $S_1 \cap S_0 = \emptyset$. Actually, the object $O_1$ is identified with its labeling $L: \mathcal{I} \rightarrow \{0, 1\}$, which is the indicator (i.e., characteristic) function of $O_1$. (That is, $O_1 = \{v \in \mathcal{I}: L(v) = 1\}$). In particular, the seeds give us a partial labeling, $L(t) = 1$ for all $t \in S_1$ and $L(t) = 0$ for all $t \in S_0$, which is propagated to all unlabeled pixels during the algorithm. All this notation may be easily extended for multiple object segmentation.

Image segmentation can be formulated as a graph cut (GC) problem subject to hard constraints. In the case of directed weighted graphs, there are two important classes of energy formulations within the Generalized GC framework, the Max-Min\(^2\) and Min-Sum optimizers (Ciesielski et al., 2012). The algorithms presented in this work are Max-Min optimizers while the classical min-cut/max-flow algorithm is a Min-Sum optimizer.

2.2 Related methods

2.2.1 Image Foresting Transform (IFT)

The Image Foresting Transform (IFT) (Falcão et al., 2004) is a modification of Dijkstra’s shortest paths algorithm (Dijkstra, 1959) allowing multiple sources and general connectivity functions (Monotonically Increasing (MI) functions). IFT uses definitions such as path, connectivity function, spanning forest and optimum path value. For a given image graph $G$, a path is a sequence of pixels $\pi = \langle t_1, t_2, \ldots, t_k \rangle$, where $(t_i, t_{i+1}) \in \mathcal{A}$, for $1 \leq i \leq k - 1$. We use $\pi_t$ to indicate that pixel $t$ is the terminus of the path. To explicitly indicate the origin of the path, we use the notation $\pi_{s \rightarrow t} = \langle s = t_1, t_2, \ldots, t_k = t \rangle$, where $s$ indicates the origin and $t$ the terminus. A path is trivial when $k = 1$. If $\pi_s$ and $\tau = \langle s, t \rangle$ are both paths, we denote as $\pi_s \cdot \tau$ the concatenation of the two paths. We denote as $\Pi(G, t)$ the set of all paths in the graph $G$ with terminus $t$, while $\Pi(G) = \bigcup_{t \in \mathcal{I}} \Pi(G, t)$ denotes all possible paths in $G$.

A spanning forest is a function $P$ that assigns to each pixel $t$ in $\mathcal{I}$ either some other adjacent pixel in $\mathcal{I}$, or a distinctive marker nil not in $\mathcal{I}$, with no containing cycles. Thus, for any pixel $t \in \mathcal{I}$, a spanning forest $P$ defines a path $\pi^P_t$ recursively as $\langle t \rangle$ if $P(t) = \text{nil}$ (root node), and $\pi^P_s \cdot \langle s, t \rangle$ if $P(t) = s \neq \text{nil}$ (predecessor node of $t$).

A connectivity function is a function $f: \Pi(G) \rightarrow \mathbb{R}$, that assigns to each path $\pi$ a path cost value $f(\pi)$. Usually, the path cost depends on the arc weights $\omega$ along the path. In this work, we use connectivity functions ($f$) constrained to paths starting in a given set of seed pixels $S \subseteq \mathcal{I}$. This constraint is modeled by defining a new path-cost function $f^S(\pi)$, which is equal to $f(\pi)$ when the origin of $\pi$ belongs to $S$, and it is equal to $+\infty$ otherwise.

\(^2\)Min-Max optimizer is a dual equivalent problem.
A path $\pi_t$ is optimum if $f(\pi_t) \leq f(\tau_t)$ for any other path $\tau_t \in \Pi(G, t)$. The optimum path value $V_{opt}(t)$ is obtained by taking to each pixel $t$ the cost of one optimum path with terminus at $t$, which is defined by $V_{opt}(t) = \min_{\forall \pi_t \in \Pi(G, t)} \{ f(\pi_t) \}$. The IFT algorithm (Algorithm 1) solves this path cost optimization problem. It receives an image graph $G$, a MI connectivity function $f$ and a set of seeds $S$, and it computes a label map $L$, a spanning forest $P: \mathcal{I} \rightarrow \mathcal{I} \cup \{ \text{nil} \}$ of optimum paths $\pi^p_t$ associated to each pixel $t \in \mathcal{I}$, and a connectivity map $V$, such that $V(t) = f(\pi^p_t)$. For the sake of simplicity, Algorithm 1 is presented here for binary segmentation.

**Algorithm 1. – General IFT Algorithm**

**INPUT:** Image graph $G = (\mathcal{N}, \mathcal{A}, \omega)$, non-empty disjoint seed sets $S_0, S_1 \subset \mathcal{N}$, and the path-cost function $f: \Pi(G) \rightarrow \mathbb{R}$.

**OUTPUT:** Optimum-path forest $P: \mathcal{N} \rightarrow \mathcal{N} \cup \{ \text{nil} \}$, the path-cost map $V: \mathcal{N} \rightarrow [-\infty, +\infty]$ and label map $L: \mathcal{N} \rightarrow \{0, 1\}$.

**Auxiliary:** Priority queue $Q$, variable $tmp$, and a status function $S: \mathcal{N} \rightarrow \{0, 1\}$, where $S(t) = 1$ for processed nodes and $S(t) = 0$ for unprocessed nodes.

1. **For each** $t \in \mathcal{N}$, **do**
2. \hspace{1em} Set $S(t) \leftarrow 0$, $P(t) \leftarrow \text{nil}$ and $V(t) \leftarrow f(\langle t \rangle)$;
3. \hspace{1em} **if** $t \in S_0$, **then**
4. \hspace{2em} $L(t) \leftarrow 0$, and insert $t$ in $Q$;
5. \hspace{1em} **if** $t \in S_1$ **then**
6. \hspace{2em} $L(t) \leftarrow 1$, and insert $t$ in $Q$.
7. **While** $Q \neq \emptyset$ **do**
8. \hspace{1em} Remove $s$ from $Q$ such that $V(s)$ is minimum;
9. \hspace{1em} Set $S(s) \leftarrow 1$;
10. **For each** $(s, t) \in \mathcal{A}$ such that $S(t) = 0$ **do**
11. \hspace{1em} Compute $tmp \leftarrow f(\pi^p_s, \langle s, t \rangle)$
12. \hspace{1em} **if** $tmp < V(t)$ **then**
13. \hspace{2em} Set $P(t) \leftarrow s$, $V(t) \leftarrow tmp$ and $L(t) \leftarrow L(s)$
14. \hspace{2em} **if** $t \notin Q$ **then** insert $t$ in $Q$.

In the case of non-MI functions, the IFT algorithm produces a spanning forest $P$, but the paths $\pi^p_t$ may not be optimum (i.e., we may have $f(\pi^p_t) = V(t) \neq V_{opt}(t)$). However, the computed spanning forest $P$ may be optimal according to other optimality criteria, as proved for the cost function of Oriented Image Foresting Transform (OIFT) (Miranda e Mansilla, 2014), as presented next.

### 2.2.2 Oriented Image Foresting Transform (OIFT)

The Oriented Image Foresting Transform (OIFT) method is build upon the IFT framework by exploring the object-contour orientation in digraphs, using non-MI connectivity functions (Miranda e Mansilla, 2014). It improves the segmentation results because it helps
to distinguish between two similar and nearby boundary segments with opposite orientations from distinct objects.

The OIFT algorithm is a Max-Min optimizer, that is, its resulting segmentation gives a global optimum solution subject to the seed constraints by maximizing the graph-cut measure $\varepsilon_{\text{min}}$ defined as:

$$
\varepsilon_{\text{min}}(L) = \min \{ \omega(s, t) : (s, t) \in A \land L(s) > L(t) = 0 \} 
$$  \hfill (2.1)

For the sake of simplicity, the OIFT algorithm is being presented here without the explicit forest calculation, from which its name comes from. We can do this, since the label map $L$ without the forest is sufficient for the segmentation task. The OIFT segmentation, indicated by $L$, can be computed by Algorithm 2, in a connected and symmetric digraph $G$, as described in Mansilla e Miranda (2013a). Alternatively, its segmentation can also be obtained by Algorithm 1, using the following non-MI connectivity function $f^*$:

$$
f^*((t)) = \begin{cases} 
-\infty & \text{if } t \in S_0 \cup S_1 \\
+\infty & \text{otherwise}
\end{cases}
$$

$$
f^*\left(\pi_{r\rightarrow s} \cdot (s, t)\right) = \begin{cases} 
\omega(s, t) & \text{if } r \in S_1 \\
\omega(t, s) & \text{otherwise}
\end{cases}
$$  \hfill (2.2)

Algorithm 2. – OIFT Algorithm

**INPUT:** Image graph $(N, A, \omega)$, non-empty disjoint seed sets $S_0$ and $S_1$.

**OUTPUT:** The label map $L: N \rightarrow \{0, 1\}$.

**AUXILIARY:** Priority queue $Q$, variable $tmp$, the cost function $V: N \rightarrow [-\infty, \infty]$, and a status function $S: N \rightarrow \{0, 1\}$, where $S(t) = 1$ for processed nodes and $S(t) = 0$ for unprocessed nodes.

1. For each $t \in N$, do
2. \hspace{1cm} Set $S(t) \leftarrow 0$ and $V(t) \leftarrow \infty$;
3. \hspace{1cm} If $t \in S_0$, then
4. \hspace{2cm} $V(t) \leftarrow -\infty$, $L(t) \leftarrow 0$, and insert $t$ in $Q$;
5. \hspace{1cm} If $t \in S_1$ then
6. \hspace{2cm} $V(t) \leftarrow -\infty$, $L(t) \leftarrow 1$, and insert $t$ in $Q$.
7. While $Q \neq \emptyset$ do
8. \hspace{1cm} Remove $s$ from $Q$ such that $V(s)$ is minimum;
9. \hspace{1cm} Set $S(s) \leftarrow 1$;
10. For each $(s, t) \in A$ such that $S(t) = 0$ do
11. \hspace{2cm} If $L(s) = 1$ then $tmp \leftarrow \omega(s, t)$
12. \hspace{2cm} Else $tmp \leftarrow \omega(t, s)$;
13. \hspace{2cm} If $tmp < V(t)$ then
14. \hspace{3cm} Set $V(t) \leftarrow tmp$ and $L(t) \leftarrow L(s)$
15. \hspace{2cm} If $t \notin Q$ then insert $t$ in $Q$. 
2.3 HIGH-LEVEL PRIORS

Note that in line 12 of Algorithm 2, the arc weight $\omega(t, s)$ of the reversed arc $(t, s)$ is used (rather than that of chosen $(s, t) \in A$). That is why a symmetric digraph is required. The value $V(t)$ assigned in line 14 constitutes a contribution, to the energy $\varepsilon_{\min}(L)$ given by (2.1), that a consecutive change of labeling $L(t)$ from $L(s)$, already fixed, to $1 - L(s)$ would represent. For every node $t$ considered in lines 10-15 the value $V(t)$ represents the worst (minimum) weight ($w_0$ or $w_1$, as defined in Remark 1) of the arcs $(v, t) \in A$ from already processed object nodes $v$ (i.e., with $S(v) = 1$).

Remark 1. Notice, that if we define the weight functions $w_0$ and $w_1$ on $A$ as $w_1(s, t) = \omega(s, t)$ and $w_0(s, t) = \omega(t, s)$, then the execution of lines 11 and 12 in Algorithm 2 is equivalent to the execution of a single line: “tmp $\leftarrow w_{L(s)}(s, t)$”. Also, if consecutive line 14 is executed, then $V(t)$ becomes $w_{L(s)}(s, t)$. In this case, the path-cost function from Equation 2.2 can also be expressed as $f^*((v_0, \ldots, v_\ell)) = w_{L(v_0)}(v_{\ell-1}, v_\ell)$ for $\ell > 0$.

In Section 2.3.1, we explain how the boundary polarity prior of OIFT is treated.

2.3 High-level priors

The usage of some prior knowledge of the objects is usually necessary in order to obtain successful segmentation results. In this section, we briefly describe some individual and structural priors used, such as boundary polarity, shape priors and geometric interactions.

2.3.1 Boundary polarity

To explore the boundary polarity, the arc weights $\omega(s, t)$ are defined as a combination of an undirected dissimilarity measure $\psi(s, t)$ between neighboring pixel $s$ and $t$, multiplied by an orientation factor, as follows:

$$\omega(s, t) = \begin{cases} 
\psi(s, t) \times (1 + \alpha) & \text{if } I(s) > I(t), \\
\psi(s, t) \times (1 - \alpha) & \text{if } I(s) < I(t), \\
\psi(s, t) & \text{otherwise},
\end{cases}$$

where $\alpha \in [-1, 1]$ and we usually have $\psi(s, t) = |I(t) - I(s)|$. Other options for $\psi(s, t)$ are discussed in (Ciesielski and Udupa, 2010; de Miranda et al., 2010). Note that, in general, we have $\omega(s, t) \neq \omega(t, s)$ for $\alpha \neq 0$. As shown in Figure 2.1(b), for $\alpha > 0$, the segmentation by OIFT favors transitions from bright to dark pixels, and $\alpha < 0$ favors the opposite orientation, as shown in Figure 2.1(c).

Finally, for multi-object segmentation we consider multiples $\alpha_i$ values, each associated to a different object.
2.3 Geodesic star convexity

Shape priors have been widely utilized in medical image segmentation to improve segmentation accuracy and robustness (Bai et al., 2017). A common shape prior is the star shape prior (SSP) (Veksler, 2008). An object has a star shape with respect to a given center \( c \) if for any point \( p \) inside the object, all points on the straight line segment between the center \( c \) and \( p \) also lie inside it (Figure 2.2).

![Star Convexity](image)

\( (a) \) Star Convexity: (a) A star-convex object. (b) Violation of the star-convexity prior, where \( p \) is a point of the given object and \( c \) is the star center considered.

The geodesic star convexity prior (GSC) corresponds to a discrete version of SSP defined directly in the image domain, by considering shortest paths in the image graph, returned by IFT with the additive path-cost function (geodesic), as the line segments. It considers all the given object seeds as center points, prioritizing the segmentation of an object with more regular shape (Mansilla et al., 2013). OIFT subject to the geodesic star convexity prior can be obtained by setting the weights of some arcs in the created digraph to \(-\infty\), according to the scheme proposed in Mansilla e Miranda (2013b), prior to computing the OIFT. For the natural image presented in Figure 2.3a, Figure 2.3b shows a segmentation result without any shape priors, while the corresponding segmentation with the GSC prior is shown in Figure 2.3c.
2.3. HIGH-LEVEL PRIORS

Figure 2.3: (a) Input image with seeds selected by the user. (b) Segmentation result by OIFT without the Geodesic Star Convexity. (c) Result by OIFT with Geodesic Star Convexity, favoring a segmentation with a more regular shape.

It is also possible to simultaneously handle boundary polarity and shape priors in OIFT, according to the results as presented in Mansilla e Miranda (2013b).

2.3.3 Geometric interactions

The contribution of Delong e Boykov (2009) for multi-object segmentation is a binary multi-layered formulation, defining a layer for each object, encoding the geometric interactions between the different objects in the image. These interactions refer to the inclusion of one object within another object or the exclusion between them, while enforcing a minimal distance between the object contours in different layers.

However, as a Min-Sum optimizer of data terms is used in Delong e Boykov (2009), their globally optimal results are restricted only to some particular cases, because it cannot always be converted to a submodular energy. For example, Figure 2.4 illustrates an example using geometric interactions between three objects: liver ($O_1$), aorta ($O_2$) and abdominal region ($O_3$), with yellow, blue and red colors respectively, where $O_1$ is excluded from $O_2$, and both are included in $O_3$. Global optimum results of the Min-Sum optimizer by Delong e Boykov (2009) cannot be obtained in this case, while our proposed approach solves this problem for the Max-Min optimizer with global optimum results (Figure 2.4b).
Figure 2.4: Example of segmentation using geometric interactions. Given an input image (a) involving three objects: liver ($O_1$), aorta ($O_2$) and abdominal region ($O_3$) with selected seeds in yellow, blue and red colors respectively. We have $O_1$ excluded from $O_2$, and both are included in $O_3$. Then, the segmentation result by our proposed method is shown in (b).
We propose the Hierarchical Layered Oriented Image Foresting Transform (HLOIFT) as a new seed-based method for multi-object segmentation (Leon e Miranda, 2017). Figure 3.1 shows an overview of our framework. For a given input image, seeds sets for some objects, and the tree of relations between objects, the HLOIFT method has the following steps: (1) Each layer is constructed as a weighted digraph representing one object with its own priors (described in Section 3.2.1). (2) HLOIFT defines a setup for the inter-layer connections representing the hierarchical constraints, such as inclusion and exclusion relations (described in Section 3.2.2). (3) HLOIFT uses an extension of the OIFT algorithm to compute an optimal cut over the hierarchical layered digraph, giving as output a labeled image (described in Section 3.2.3).

We first present some required notations and definitions.
CHAPTER 3. PROPOSED METHOD

3.0 INPUT

. Image: I
. Set of seeds
. Priors for objects
. Tree of Relations: h
. Parameter of distance: p

3.0 HLOIFT

1*. Set of object-digraph construction
2*. Hierarchical digraph construction
3*. Energy optimization

3.0 OUTPUT

. Labeled image

Figure 3.1: Overview of our framework. Given the input parameters, a hierarchical weighted digraph of layers (digraphs) is constructed using the inclusion (solid line) and exclusion (dashed line) hierarchical constraints between objects, and a graph-cut measure is optimized by our algorithm. Finally, we have a labeled image as output. (Compare to Figure 4.13. Notice, that only three seeds are used.)
3.1 Notations and definitions

Let \( \mathcal{L} = \{1, \ldots, m\} \) denote an index set, where each element in \( \mathcal{L} \) is associated with an object we consider and \( m \) is the number of objects to be segmented.

The HLOIFT graph associated with \( \mathcal{L} \) and image \( (\mathcal{I}, I) \) will be defined on the set of nodes \( \mathcal{N} = \mathcal{L} \times \mathcal{I} \). The HLOIFT resulted segmentation of the image will be identified with a binary variable \( X: \mathcal{N} \to \{0, 1\} \), where, for \( i \in \mathcal{L} \) the \( i \)th object \( O_i \) and the background \( O_0 \) are defined, respectively, as

\[
O_i = \{ t \in \mathcal{I} : X(i,t) = 1 \} \quad \text{and} \quad O_0 = \mathcal{I} \setminus \bigcup_{i \in \mathcal{L}} O_i.
\]  

(3.1)

Each object/background \( O_i, i \in \mathcal{L} \cup \{0\} \), will be identified with a corresponding set \( S_i \subset \mathcal{I} \) of seeds, aiming for \( S_i \subseteq O_i \). Only the seed sets \( S_i \) for the leaves in the tree of relations and background must be non-empty, since nested boundaries can be discovered by the inclusion relation as will be demonstrated in the experiments.

The hierarchy between the objects is understood as a prior knowledge on any pair \( \langle O_i, O_j \rangle \) of objects we consider: either \( O_i \cap O_j = \emptyset \), or one of them is properly contained in the other. This prior is represented as a function \( h: \mathcal{L} \to \{1, \ldots, m+1\} \), referred to as a tree, and defined as follows. If \( O_{m+1} = \mathcal{I} \) (the image domain and the root of the tree), then \( h(i) = j \) if, and only if, \( O_j \) is the smallest of the objects properly containing \( O_i \). If \( h(i) = j \), then we will refer to \( O_j \) as the parent of \( O_i \) (or say that the tree node \( j \) is the parent of \( i \)). See the left lower part of Figure 3.1 for a graphical representation of \( h \). We say that the objects \( O_i \) and \( O_j \) (or just nodes \( i \) and \( j \)) are siblings, provided \( i, j \in \mathcal{L} \) are distinct and \( h(i) = h(j) \). In particular, any sibling objects are disjoint.

In addition, we will use the distance parameter \( \rho \geq 0 \), which indicates the minimum distance between the boundaries of siblings and of the parent-offspring pairs of objects. More specifically,

(C) for siblings \( O_i \) and \( O_j \) we will assume that \( \| s - t \| > \rho \) for every \( s \in O_i \) and \( t \in O_j \), while for parent-offspring pair \( \langle O_j, O_i \rangle \) (i.e., with \( h(i) = j \)) that \( t \in O_j \) whenever there exists an \( s \in O_i \) with \( \| s - t \| \leq \rho \).

The hierarchy \( h \), with no parameter \( \rho \), is understood as the consistency condition (C) with \( \rho = 0 \). For \( \rho > 0 \), we require that the assumptions of \( h \) are, in a sense, strongly satisfied.

3.2 Hierarchical Layered OIFT (HLOIFT)

We present next the steps of our proposed method.
3.2.1 Construction of the layers of our digraph

The first step of HLOIFT is to create a set of $m$ layers, where each layer $\mathcal{H}_i$, $i \in \mathcal{L}$, is used to represent a single corresponding object $O_i$. A layer $\mathcal{H}_i = (\mathcal{N}_i, \mathcal{A}_i, \omega_i)$ is a weighted digraph, where $\mathcal{N}_i = \{i\} \times \mathcal{I}$ and each node $t = (i, v) \in \mathcal{N}_i$ corresponds to the image pixel $p(t) = v$. Thus, the node set $\mathcal{N}$ of HLOIFT digraph is defined as $\mathcal{L} \times \mathcal{I} = \bigcup_{i \in \mathcal{L}} \mathcal{N}_i$ and $p: \mathcal{N} \to \mathcal{I}$ is the projection onto the second coordinate. See graphical representation of layers in Figures 3.2, 3.3, and 3.4. Also, $\lambda: \mathcal{L} \times \mathcal{I} \to \mathcal{L}$ will denote the projection onto the first coordinate, that is, $\lambda(t) = i$ means that $t$ belongs to the $i$th layer of the graph.

Let $\mathcal{A}_T$ be an affinity defined on the original image graph (with $\mathcal{N} = \mathcal{I}$) as in the case of OIFT. We will usually assume that, in the case of 2D images, $\mathcal{A}_T$ is the 4- or 8-neighborhood adjacency. We define the intra-layer adjacency $\mathcal{A}_i$ on $\mathcal{N}_i$ as this $\mathcal{A}_T$, that is, $(s, t) \in \mathcal{A}_i$ if, and only if, $(p(s), p(t)) \in \mathcal{A}_T$. Similarly, if for an $i$th object we already have defined a weight function $\omega_i$ on the image (depending on the image intensities and, in some cases, according to a given higher level prior), then the intra-layer weight function $\omega_i$ is defined, for every $(s, t) \in \mathcal{A}_i$, as $\omega_i(s, t) = \omega_i(p(s), p(t))$. For HLOIFT to work properly we need to assume that the values of these intra-layer weight functions are the finite real numbers (unless they represent hard constraints, see star convexity constraint next), as opposed to the inter-layer weight, defined below, which will have infinite values.

Of course, $\omega_i$ should highlight the desired boundaries for $O_i$ as clearly as possible and we would like to incorporate in its definition the higher level priors whenever it is appropriate. In particular, to utilize the object-contour orientations, that is, the boundary polarity priors, we use in our experiments the same scheme that was adopted by the regular OIFT method, defining $\omega_i$ via formula (2.3) with $\psi(s, t) = ||I(s) - I(t)||$. (For other possible definitions of $\psi$ see, e.g., (Ciesielski e Udupa, 2010; de Miranda et al., 2010).) In this setting, each object $O_i$ has its own constant $\alpha_i \in [-1, 1]$ (used in (2.3)), so that we can favor the segmentation of $O_i$ with transitions from bright to dark pixels with $\alpha_i > 0$, or the opposite orientation, with $\alpha_i < 0$. Note that $\alpha_i = 0$ can be used to indicate that $O_i$ has no boundary polarity prior.

If the $i$th layer is created using the Geodesic Star Convexity prior (GSC), then we will be prioritizing the segmentation of $O_i$ with more regular shape. A common shape prior is the star shape prior (SSP) (Veksler, 2008), where a region has a star shape with respect to a given center $c$ if for any point $p$ inside the region, all points on the straight line segment between the center $c$ and $p$ also lie inside the region. The geodesic star convexity prior (GSC) corresponds to a discrete version of SSP directly in the image domain, by considering shortest paths in the image graph, returned by IFT with the additive path-cost functions, as the line segments. It considers all the given seeds as center points of a region, prioritizing the segmentation of the region with more regular shape. The geodesic star convexity prior for the $i$th layer is obtained by setting the weights $\omega_i$ of some arcs in $\mathcal{H}_i$ to $-\infty$, according to the scheme proposed in Mansilla et al. (2013). Moreover, it is still possible to simultaneously handle boundary polarity and shape priors (Mansilla e Miranda, 2013b).
3.2.2 Hierarchical digraph construction (setup of inter-layer connections)

In this step, HLOIFT generates a hierarchical layered weighted digraph $H = (N, A, \omega)$ as the union of all layered graphs $H_i$, $i = 1, \ldots, m$, with additional interlayer arcs connecting only some of the distinct layers. The choice of these arcs, as well as their weights chosen among $-\infty$ and $\infty$, is subjugated to a sole requirement of ensuring the agreement of a resulted segmentation with assumed hierarchical priors $h$ and its related parameter $\rho$.

Specifically, the vertices $s \in N_i$ and $t \in N_j$, with distinct $i, j \in L$, form an inter-layer arc whenever, according the hierarchy consistency condition (C), a decision whether one of them belongs (or not) to the object in question may force such decision for the other vertex. Formally, this means that a pair $\langle s, t \rangle$ is an inter-layer arc in $H$ (i.e., $\langle s, t \rangle$ belongs to $A$ of $H$) if, and only if, $\|p(s) - p(t)\| \leq \rho$ and either $O_i$ and $O_j$ are siblings, or one of them is the parent of the other. The set of all inter-layer arcs coming from the siblings is denoted by $A_s$, while $A_p$ will stand for those associated with a parent/offspring pair. The weights of these inter-layer arcs $\langle s, t \rangle$, with $s \in N_i$ and $t \in N_j$ (or, equivalently, with $\lambda(s) = i$ and $\lambda(t) = j$), are defined as follows.

- **Inclusion.** If $O_j$ is the parent of $O_i$ (i.e., $h(i) = j$), then we define $\omega(t, s) = \infty$ and $\omega(s, t) = -\infty$. Figure 3.2 shows, in this case, the arcs and their weights, where the inter-layer arcs are formed according to a 4-neighborhood adjacency and the parameter $\rho$ is equal 1.

![Figure 3.2: Illustration of inter-layer arc construction, involving two objects $O_i$ and $O_j$, for the inclusion case ($O_j$ is the parent of $O_i$, i.e., $h(i) = j$), where $\omega(s, t) = -\infty$ and $\omega(t, s) = \infty$ for $\lambda(s) = i$ and $\lambda(t) = j$.](image)

- **Exclusion.** If the objects $O_i$ and $O_j$ are siblings, then we put $\omega(s, t) = \omega(t, s) = -\infty$. See Figure 3.3.

Notice that, in the inclusion case, the pair $\langle s, t \rangle$ contradicts the consistency requirement (C) if, and only if, the associated cost of the arc in the cut has value $-\infty$. This will be used in the specific formulation of our algorithm HLOIFT (especially extra condition in line 13) and in the proof of our correctness theorem. Basically, the weight $-\infty$ enforces that the
3.2 Layer $i$ - Layer $j$ - $\infty$

$\rho = 1$

Figure 3.3: Illustration of inter-layer arc construction, involving two objects $O_i$ and $O_j$, for the exclusion case ($O_i$ and $O_j$ are siblings), where $\omega(s,t) = -\infty$ for all inter-layer arcs $(s,t)$.

vertex connected to one just processed will be examined with the highest possible priority, to ensure satisfaction of the consistency requirement (C).

In Figure 3.4, we give an example of the hierarchical layered digraph construction for a case that cannot be optimized under the graph cut framework of Delong e Boykov (2009). This case combines the inclusion and exclusion hierarchical constraints, such that we have two mutually exclusive objects $O_i$ and $O_j$, both contained within another object $O_k$. Globally optimal segmentation in this case cannot be modeled with graph cuts, because it cannot be converted to a submodular energy, more details in Delong e Boykov (2009). The proposed HLOIFT method can compute globally optimal results in this case and also in other more sophisticated cases, as described below.

Figure 3.4: Illustration of the inter-layer arc construction, involving three objects $O_i$, $O_j$ and $O_k$, where $O_k$ is the parent of two sibling objects, $O_i$ and $O_j$, i.e. $h(i) = h(j) = k$.

3.2.3 Energy optimization

In the final step, we execute the HLOIFT algorithm (Algorithm 3), which constitutes a modified OIFT algorithm from (Mansilla e Miranda, 2013a; Miranda e Mansilla, 2014). It is applied to the hierarchical layered graph $\mathcal{H}$ constructed above and its output maximizes
a single energy $\varepsilon_{\min}^h$ (i.e., the solution $X$ by HLOIFT is such that $X = \arg\max_{X'} \varepsilon_{\min}^h(X')$, among all solutions $X'$ satisfying the seed constraints), a modification of energy $\varepsilon_{\min}(L) = \min\{\omega(s, t): (s, t) \in \mathcal{A} \land L(s) > L(t) = 0\}$ defined in (2.1). This modification of $\varepsilon_{\min}$ is designed to ensure that the output satisfies also the hierarchical constraints imposed by $h$ and $\rho$.

Specifically, for a binary map $X: \mathcal{N} \rightarrow \{0, 1\}$ described in Section 3.1 the energy $\varepsilon_{\min}^h$ of $X$ is defined as

$$\varepsilon_{\min}^h(X) = \min\{\varepsilon_{\min}^{\text{incl}}(X), \varepsilon_{\min}^{\text{excl}}(X)\}, \quad (3.2)$$

where

$$\varepsilon_{\min}^{\text{incl}}(X) = \min\{\omega(s, t): (s, t) \in \mathcal{A} \setminus \mathcal{A}_s \land X(s) > X(t)\},$$

$$\varepsilon_{\min}^{\text{excl}}(X) = \min\{\omega(s, t): (s, t) \in \mathcal{A}_s \land X(s) = X(t) = 1\}.$$

In other words, all arcs in the cut, except for the inter-layer arcs $\mathcal{A}_s$ associated to siblings, are treated directionally, in the same way as in $\varepsilon_{\min}$. This part is expressed by the energy $\varepsilon_{\min}^{\text{incl}}$. However, the inter-layer arcs from $\mathcal{A}_s$ must be treated differently. First of all, there is not directional information between them. Moreover, the siblings $s$ and $t$ influence one another, according to (C), only when they both belong to their respective objects, that is, when $X(s) = X(t) = 1$. This justifies the format of $\varepsilon_{\min}^{\text{excl}}$. The formula for the combined energy $\varepsilon_{\min}^h$ is defined as a minimum of the costs of all relevant arcs in the cut, the same way as in $\varepsilon_{\min}$ (only the meaning of the term “relevant” being changed).

We say that a sequence $\langle S_0, \ldots, S_m \rangle$ of seed sets is consistent with (C) (with respect to $h$ and $\rho$) provided $S_i \neq \emptyset$ for $i = 0$ and every $i \in \mathcal{L}$ with no offsprings and there exists a sequence $\langle O_0, \ldots, O_m \rangle$ satisfying (C) such that $S_i \subseteq O_i \subset \mathcal{I}$ for every $i \in \mathcal{L} \cup \{0\}$.

**Theorem 1** (Cut optimality by HLOIFT). For every image $(\mathcal{I}, I)$, a hierarchy tree $h$, a distance parameter $\rho \geq 0$, and a sequence $\langle S_0, \ldots, S_m \rangle$ of seed sets consistent with (C), the binary map $X: \mathcal{N} \rightarrow \{0, 1\}$ computed by Algorithm 3 maximizes the energy $\varepsilon_{\min}^h(X)$ given by (3.2) among all solutions satisfying the seed constraints and the consistency requirement (C).
Algorithm 3. – HLOIFT Algorithm

INPUT: Hierarchical layered digraph $H = (\mathcal{N}, \mathcal{A}, \omega)$, builded from an image according to the tree $h$ of hierarchical constraints and the distance parameter $\rho$; the seed sets $\langle \mathcal{S}_0, \ldots, \mathcal{S}_m \rangle$ consistent with (C).

OUTPUT: The binary map $X : \mathcal{N} \rightarrow \{0, 1\}$ identifying segmentation given by (3.1).

Auxiliary: Priority queue $Q$, variable $tmp$, the cost map $V : \mathcal{N} \rightarrow [\infty, \infty]$, and an array of status $S : \mathcal{N} \rightarrow \{0, 1\}$, where $S(t) = 1$ for processed nodes and $S(t) = 0$ for unprocessed nodes.

1. For each $t \in \mathcal{N}$ and $i \in \mathcal{L}$ do
   2. Set $S(t) \leftarrow 0$ and $V(t) \leftarrow \infty$;
   3. If $p(t) \in \mathcal{S}_0$ then
      4. $V(t) \leftarrow -\infty$, $X(t) \leftarrow 0$, and insert $t$ in $Q$;
   5. If $p(t) \in \mathcal{S}_i$ and $\lambda(t) = i$ then
      6. $V(t) \leftarrow -\infty$, $X(t) \leftarrow 1$, and insert $t$ in $Q$.
   7. While $Q \neq \emptyset$ do
      8. Remove $s$ from $Q$ such that $V(s)$ is minimum;
      9. Set $S(s) \leftarrow 1$;
     10. For each $(s, t) \in \mathcal{A}$ such that $S(t) = 0$ do
        11. If $X(s) = 1$ then $tmp \leftarrow \omega(s, t)$
        12. Else $tmp \leftarrow \omega(t, s)$;
        13. If $tmp < V(t)$ and $\neg [(s, t) \in \mathcal{A}_s$ and $X(s) = 0]$, then
           14. Set $V(t) \leftarrow tmp$ and $X(t) \leftarrow X(s)$;
           15. If $t \notin Q$ then insert $t$ in $Q$;
           16. If $(s, t) \in \mathcal{A}_s$ and $X(s) = 1$ then
              17. $X(t) \leftarrow 0$.

Algorithm 3 is essentially identical to Algorithm 2 after we disregard lines 16-17 and the extra condition on line 13. More specifically, if we have only one object (i.e., $\mathcal{L} = \{1\}$), then $X = L$ and the condition from line 16 is never satisfied, so lines 16-17 can be removed. More generally, lines 16-17 and the extra condition on line 13 are redundant when tree $h$ has no siblings. In this case, the optimality of HLOIFT regarding the maximization of $\varepsilon^h_{\min}(X)$ can be deducted from Theorem 2 from Mansilla e Miranda (2013a).

In line 16 the condition is satisfied when $s$ and $t$ are siblings and $p(s) \in O_{\lambda(s)}$ as $X(s) = 1$. Therefore, in line 17 we impose $X(t) = 0$, to ensure that $p(t) \notin O_{\lambda(t)}$, as required by (C). More specifically, lines 16-17 ensure that for the output $X$ we have no $(s, t) \in \mathcal{A}_s$ with $X(s) = X(t) = 1$, that is, $\varepsilon^h_{\min}(X) = -\infty$.

Concerning the computational complexity, HLOIFT is $O(M + N)$, where $N$ is the number of vertices in the graph $H$ and $M$ is the number of arcs in the graph $H$, when $Q$ is implemented using bucket sorting (Falcão et al., 2004) and $O(M + N \log N)$ (linearithmic

\textsuperscript{1}In fact, the check condition $X(s) = 1$ on line 16 of Algorithm 3 is not strictly necessary. We are keeping it only to facilitate the understanding.
time) if $Q$ is a heap. The Graph cut computational complexity is $O(\sqrt{M} \ast N^2) = O(N^{2.5})$ when $H$ is a sparse graph, which is more than quadratic-time using a push-relabel based on the highest label node selection rule (Boykov e Kolmogorov, 2004).

As a final note, observe that an interesting variation of Algorithm 3 could be considered. Specifically, in the case of inclusion relation $h(i) = j$, we can additionally require that the seeds in $S_j$ belong exclusively to the parent object (i.e., $O_i \cap S_j = \emptyset$). In other words, $S_j$ should be inserted as background seeds on its children’s layers to additionally impose that the seeds in $S_j$ do not belong to the offspring objects of $j$.

### 3.3 Extensions of HLOIFT

#### 3.3.1 3D HLOIFT

A 3D image is a pair $(I, I)$, where $I$ is a finite set of voxels identified with the 3-tuples of integers (i.e., $I \subset \mathbb{Z}^3$) and $I$ is a mapping that assigns to each voxel $t \in I$ its intensity $I(t)$, that is, either a real number (in case of monochromatic image) or an appropriate vector in $\mathbb{R}^k$.

From the implementation point of view, the only required changes of HLOIFT for the segmentation of 3-dimensional images (volumes) are that now each layer has intra-layer arcs in a 3D neighborhood and that the parameter $\rho$ defines a sphere in space.

#### 3.3.2 HLOIFT with superpixels

Here, we propose a superpixel-based adaptation of the HLOIFT method, leading to a more efficient and adequate solution for multi-object segmentation in large images.

Superpixels can group pixels into perceptually meaningful atomic regions of similar and connected pixels. Superpixel primitives are computationally much more efficient than their pixel counterparts. For instance, superpixels can be used to create a Region Adjacency Graph (RAG) greatly reducing the number of graph elements.

The superpixels are given by an unsupervised segmentation from a given image. The most popular method for superpixel generation is SLIC, which starts with a selection of $k$ initial cluster centers, which are sampled on a regular grid spaced $\sqrt{|I|}/k$ nodes apart. Then, for the assignment step of each pixel to a cluster/superpixel, an adaptive $k$-means clustering is used for SLIC.

In this work we used IFT-SLIC (Alexandre et al., 2015), which combines benefits from both IFT (Image Foresting Transform) and SLIC (Simple Linear Iterative Clustering) (Achanta et al., 2012) to compute superpixels from a given input image.

IFT-SLIC converts the color space of the input image to CIELAB, in the case of colored images, and starts with a selection of $k$ initial cluster centers similar to SLIC. Then, for the assignment step of each pixel to a cluster, instead of using an adaptive $k$-means clustering.
such as SLIC, IFT-SLIC considers IFT computations with a non-MI connectivity function, featuring a parameter that controls the boundary adherence and compactness of the generated clusters. Then each cluster center is updated to be the closest pixel to its mean position and the process is repeated for a total of \( n \) iterations.

Similarly to HLOIFT at the pixel level described before, the HLOIFT at superpixel level is composed of three steps and produces a labeled image as result.

**Set of object-digraph construction** We first create a set of \( m \) weighted digraphs of superpixels \( \mathcal{H}_i, i = 1, \ldots, m \), where each digraph corresponds to a single object \( O_i \) of an \((n\text{-dimensional})\) image \((\mathcal{I}, \mathcal{I})\). Each graph \( \mathcal{H}_i = (\mathcal{N}_i, \mathcal{A}_i, \omega_i) \) is a triple consisting of a vertex set \( \mathcal{N}_i \), a directed edge set \( \mathcal{A}_i \) and a weight function \( \omega_i \). Each pair \((\mathcal{N}_i, \mathcal{A}_i)\) is an isomorphic copy of a Region Adjacency Graph (RAG) of the given image \((\mathcal{I}, \mathcal{I})\) segmented in superpixels by IFT-SLIC (Alexandre et al., 2015), while \( \omega_i \) is a defined weight function for every \((s, t) \in \mathcal{A}_i\), being \( p(s) \) and \( p(t) \) the corresponding superpixels of nodes \( s \) and \( t \). For example, we may consider \( \omega_i(s, t) = |I(p(s)) - I(p(t))|\), where \( I(p(t)) \) is the mean intensity inside superpixel \( p(t) \). Of course, \( \omega_i \) should also highlight the priors for each object \( O_i \) whenever it is appropriate. For this purpose, we consider the same modification scheme of the weight assignment that was adopted by the regular OIFT method (Miranda e Mansilla, 2014) for boundary polarity priors, where the polarity of each \( O_i \) is defined to highlight boundary transitions from bright to dark superpixels or from dark to bright.

**Hierarchical digraph construction** In this step, we generate a hierarchical weighted digraph \( \mathcal{H} = (\mathcal{N}, \mathcal{A}, \omega) \) as the union of all object-digraphs of superpixels \( \mathcal{H}_i, i = 1, \ldots, m \), with additional arcs connecting only some of the distinct object-digraphs, based on the priors given by the parent tree \( h \) and the parameter \( \rho \geq 0 \) representing the minimal distance between the object boundaries. The hierarchical prior between any pair \((O_i, O_j)\) of objects is understood as an exclusion case when \( O_i \cap O_j = \emptyset \), or as an inclusion case when one of them is properly contained in the other. For convenience, object \( O_{m+1} = \mathcal{I} \) is considered to be the root of the tree representing the image domain. The notation \( h(i) = j \) indicates that \( O_i \subset O_j \), being \( O_j \) the parent of \( O_i \) and we say that two objects \( O_i \) and \( O_j \) are siblings if \( h(i) = h(j) \), meaning that both have the same parent. The weights of the arcs for the inclusion case are given by \( \omega(s, t) = -\infty \) and \( \omega(t, s) = \infty \) for \( h(i) = j, s \in \mathcal{N}_i \) and \( t \in \mathcal{N}_j \), whenever the superpixels \( p(s) \) and \( p(t) \) have pixels with a distance smaller than \( \rho \). For the exclusion case we consider \( \|p - q\| > \rho \) for every pixels \( p \in O_i \) and \( q \in O_j \). Therefore, for the exclusion case, we have special arcs to avoid overlapping between sibling objects, defining \( \omega(s, t) = \omega(t, s) = -\infty \), whenever superpixels \( p(s) \) and \( p(t) \) have pixels with a distance smaller than or equal to \( \rho \). Under this scheme, it is possible to have many different and sophisticated cases of hierarchical constraints which cannot be easily modeled with graph cuts (Delong e Boykov, 2009).

**Energy optimization** Finally, we execute our proposed method using an algorithm similar
to Algorithm 3, as presented in Chapter 3, but running on the hierarchical weighted digraph of superpixels $\mathcal{H}$ as constructed here. Its output maximizes a single energy defined to ensure that the output satisfies all the constraints, including the constraints imposed by $h$ and $\rho$, according to the theoretical result presented in Leon et al. and Appendix A.
In this chapter, an experimental evaluation of HLOIFT is presented.

First, we analyze the effects of different high-level priors on the segmentation results, showing that HLOIFT is a versatile method, which allows us to customize the segmentation to some target objects according to their global properties (shape and polarity). Then, we assess the performance of HLOIFT against the previously existing method for multiple object segmentation by IFT (Miranda e Falcão, 2009) and the segmentation of multiple objects by the hierarchical min-cut/max-flow algorithm (Delong e Boykov, 2009).

We also evaluate the usage of HLOIFT in 3-dimensional images (volumes). The main challenges correspond to the required space and execution time, since in multidimensional data the memory consumption grows exponentially with the increase in the number of dimensions. Here we present the results of applying HLOIFT to 3D volumes, through the direct application of its proposed algorithm, without taking any additional precautions to get a more moderate usage of memory, in order to test its viability in this more challenging scenario.

Finally, we present experimental results for the superpixel-based adaptation of the HLOIFT method, leading to a more efficient and adequate solution for multi-object segmentation in large images, and show the improvement in the running time.

4.1 2D experimental evaluation

4.1.1 Setting the high-level priors

The proper configuration of the high-level priors for each object is essential to obtain the desired segmentation of the target objects. Figure 4.1 shows a two-object segmentation problem for a synthetic image composed of four nested boundaries. We present the results using one internal seed for the object $O_1$, an external seed for the background, the inclusion relation $h(1) = 2$, $\rho = 1.5$ and $\omega_i$ defined via formula (2.3) with $\psi(s, t) = |I(s) - I(t)|$. HLOIFT with different priors for each object can provide any desired result, allowing the easy customization of the segmentation to any particular result. For example, Figure 4.1(a)
shows the result when $O_1$ has boundary polarity setup from bright to dark and $O_2$ from dark to bright, while Figure 4.1(d) shows the result for the opposite orientation.

Priors: (a) $-O_1^{bd}, O_2^{db}$  
(b) $-O_1^{bd}, O_2^{gdb}$  
(c) $-O_1^{bd}, O_2^{gbd}$  
(d) $-O_1^{bd}, O_2^{bd}$  
(e) $-O_1^{g}, O_2^{g}$

**Figure 4.1:** Example of two object segmentation by HLOIFT, where $O_2$ is parent of $O_1$. Each object has different high-level priors –db: polarity from dark to bright pixels, bd: polarity from bright to dark pixels and g: geodesic star convexity prior.

Another important parameter is the $\rho$ value, which controls the minimum distance between the object boundaries. In order to understand its effect on the results, Figure 4.2 shows HLOIFT with geodesic star convexity prior to segment an image of archaeological fragments (Figure 4.2a), with three sibling objects, using the simplest arc weights $\omega_i(s, t) = |I(t) - I(s)|$ (Figure 4.2b). For $\rho = 0$, we get a bad result with touching objects (Figure 4.2c), which can be avoided by using $\rho = 2$ (Figure 4.2d).

4.1.2 Qualitative comparison with the IFT method

In this section, we compare the results obtained by HLOIFT against the IFT method (Miranda e Falcão, 2009) for multi-object segmentation by seed competition, which encompasses the watershed transform from markers. OIFT is not included here since it is restricted only to binary segmentation (Mansilla e Miranda, 2013a). We used for this experiment medical images, composed of multiple sophisticated objects.

Figure 4.3 shows an image segmentation task, using $\omega_i$ defined via formula (2.3) with $\psi(s, t) = |I(s) - I(t)|$, where the goal is to segment a gray-scale CT image composed of three regions, $O_1$ (central bone), $O_2$ (patella) and $O_3$ (knee), which are shown in yellow, blue and red color, respectively. The first row shows the results for the IFT method by seed competition, with user provided markers for the three objects, plus one additional external marker for the background. In this example, HLOIFT requires markers only for the two inner objects and for the background, as shown on the second row. For HLOIFT, we considered $\rho = 1.5$ and the geodesic star convexity with boundary polarity from bright to dark ($g + bd$) for all objects ($\alpha = 0.75$). In the second column, we can observe the differences highlighted in the $O_1$’s contour. IFT gives a poor result for $O_1$, mixing bright and dark boundaries, because it does not support the boundary polarity prior. On the other hand, HLOIFT can be seen as an extension of OIFT for multiple object segmentation, allowing different priors for each object, giving better results and requiring fewer seeds.

Figure 4.4 shows the segmentation of a MRI slice of a real foot, using $\omega_i$ defined via formula (2.3) with $\psi(s, t) = G(s) + G(t)$, where $G(.)$ denotes the magnitude of the Sobel gradient. The objects of interest are the two large bones in the peritalar complex, namely, the talus ($O_1$) and the calcaneus ($O_2$). These objects are modeled as siblings, i.e., both have the same parent (image domain). We used for HLOIFT, the exclusion relation $h(1) = h(2)$, $\rho = 0$, the geodesic star convexity and boundary polarity ($\alpha = -0.75$). IFT gives worse results, capturing good part of the background as part of the objects, while HLOIFT gives a more regular and correct segmentation.

Figure 4.5 shows a segmentation task of a CT image composed of three objects, liver ($O_1$), aorta ($O_2$) and the abdominal region ($O_3$), which are shown in yellow, cyan and red color, respectively. The liver ($O_1$) and aorta ($O_2$) are modeled as two sibling objects contained in the abdomen ($O_3$), as defined by $h$. We used $\omega_i$ defined via formula (2.3) with $\psi(s, t) = G(s) + G(t)$, where $G(.)$ denotes the magnitude of the Sobel gradient. For the same user provided seeds, the IFT gets unsatisfactory results, while HLOIFT can effectively explore the inclusion and exclusion relations with $\rho = 0$, the geodesic star convexity, and the boundary polarity from bright to dark pixels ($\alpha = 0.75$) for the three objects leading to superior results.
Figure 4.3: Knee segmentation composed of three objects in a CT image, including the patella in blue. (a-b) Result by IFT where the $O_1$ is mixing bright and dark boundaries. (c-d) An improved result for the central bone is obtained by HLOIFT with boundary polarity from bright to dark pixels, requiring fewer seeds.

Figure 4.4: Talus ($O_1$) and calcaneus ($O_2$) segmentation. The two objects are siblings. For HLOIFT, we used $\rho = 0$, the geodesic star convexity and boundary polarity ($\alpha = -0.75$).

In Figure 4.6, we use an axial cross section of a thoracic-abdominal CT image extracted from an open database called 3D-IRCADb-02 (Soler et al., 2012) to segment six objects: right lung ($O_1$), liver ($O_2$), heart ($O_3$), left lung ($O_4$), aorta ($O_5$) and the thoracic-abdominal
Figure 4.5: Liver ($O_1$), aorta ($O_2$) and abdomen ($O_3$) segmentation on a CT slice image. For HLOIFT, we used $\rho = 0$, $h(1) = h(2) = 3$ and the geodesic star convexity shape prior with the bright to dark boundary polarity ($\alpha = 0.75$).

As input we have the image, the tree of relations ($h$) and some user seeds. We used $\omega_i$ defined via formula (2.3) with $\psi(s, t) = |I(s) - I(t)|$. For HLOIFT, we used $\rho = 3.5$, boundary polarity from dark to bright pixels for $O_1$, $O_4$ shape constraint by geodesic star convexity for $O_2$ and $O_3$, and boundary polarity from bright to dark pixels for $O_5$ and $O_6$. It can be seen, the results obtained by HLOIFT are closer to the ground-truth compared to the IFT results.
4.1.3 Comparison with multi-object segmentation by min-cut/max-flow algorithm

In this section, we compare HLOIFT with multi-object segmentation by the min-cut/max-flow algorithm in layered graphs (Delong e Boykov, 2009). For the sake of simplicity, we considered only the inclusion relation, since many cases combining the inclusion and exclusion hierarchical constraints, such that when we have two mutually exclusive objects $O_i$ and $O_j$,
both contained within another object $O_k$, cannot be converted to a submodular energy to perform the optimization by the graph-cut framework (Delong e Boykov, 2009). We used the max-flow/min-cut code from (Boykov e Kolmogorov, 2004).

Figure 4.7 shows a flower segmentation using $\omega_i(s,t) = G(s) + G(t)$, where $G(.)$ denotes the maximum magnitude of the Sobel gradient for the three image channels. We used $p = 1.5$ and no region constraints (shape constraints/boundary polarity). In general the results are similar for both methods. The min-cut/max-flow algorithm generates results with a smoother contour, but sometimes this can lead to errors in some finer parts of the object, such as the petals (Figure 4.7b).

![Flower segmentation in two objects, the central part in cyan and the petals in yellow, using the inclusion relation. (a) The input image. (b) Result by the min-cut/max-flow algorithm in layered graphs. (c) Result by HLOIFT.](image)

Besides being able to compute globally optimal results with arbitrary hierarchy constraints, the proposed HLOIFT method also has a better running time compared to the min-cut/max-flow algorithm. Table 4.1 shows the running times for the flower segmentation using different image resolutions in a laptop Intel Core i3-5005U CPU 2.00GHz ×4.

4.1.4 Quantitative accuracy experiments

For quantitative accuracy results, we compared HLOIFT, with the multi-object segmentation by IFT (Miranda e Falcão, 2009), its improved version by the relaxation procedure proposed by Malmberg et al. (2010), and the hierarchical layered graph cut (Delong e Boykov, 2009; Delong et al., 2012), denoted as HLGC, using two datasets of medical images.

For fair comparison, only methods with the same type of user input were considered here, in the form of a partial labeling. In order to stress the methods to their limit, in a more challenging situation, we only consider simple arc weights with $\psi(s, t) = |I(s) - I(t)|$, so that no a priori information on the brightness (or color/texture) distribution was taken into account (de Miranda et al., 2010), nor enhancements based on deep learning techniques (Wolf et al., 2017; Wolf et al., 2019).

For the first dataset, we used 40 slices from thoracic CT studies of size $512 \times 512$ to segment the liver and the abdomen as its parent object. The second dataset was composed of 40 real MR images to segment the talus and calcaneus bones as siblings, taking the foot region as their parent. The same seeds were used for all the methods, which were progressively obtained by eroding the ground truth objects and background for different radius sizes (Figure 4.8a). Figure 4.8 illustrates an example of the segmentation of the liver and abdomen for different methods. For the bones we used $\alpha = -0.5$ and $\rho = 3$ pixels, while for the liver we used $\alpha = 0.9$ and $\rho = 5$ pixels. HLGC could not exploit the exclusion relation for the bones, since it cannot be converted to a submodular energy for these sibling objects inside the foot.

The mean accuracy curves according to the Dice coefficient are shown in Figure 4.9, being the results in the left column obtained without shape constraints and the ones in the right with Geodesic Star Convexity (GSC). The accuracy curves for the parent objects (foot and abdomen) are not shown, since they had almost perfect results (Dice $> 99\%$). HLOIFT had the best results in most cases. Note also that it could benefit more from the usage of the shape constraint by GSC for the liver compared to HLGC, since this latter approach was already producing an object with regular shape and therefore was almost not affected by the inclusion of GSC.

1Note that drawing scribbles for a partial labeling with a large brush can be quite effective to quickly mark several object/background pixels, while accurately selecting extreme boundary points requires more user attention and caution. Therefore comparing these different types of constraints is quite subjective.
Figure 4.8: (a) Seeds obtained by eroding the ground truth of each object/background with 48 pixels radius. (b) Multi-object result by IFT. (c) The result by hierarchical layered graph cut (HLGC) mistakenly assigns the aorta as part of the liver. (d) A better result is obtained by HLOIFT.
Figure 4.9: The mean curves of Dice accuracy for different methods.
4.2 3D experimental analysis

We present an experimental analysis of HLOIFT in 3-dimensional images (volumes) to assess its performance considering different high-level priors. We use a synthetic image of size $150 \times 150 \times 150$ voxels composed of six distinct regions: Two dark cubes contained in a brighter ball, which in turn is contained inside a bigger cube, surrounded by a white background, and a small ball contained in one of the inner cubes. Then, we want to segment it into three objects, where $O_1$ and $O_2$ are included in $O_3$. By changing the boundary polarity prior from “bright to dark” (bd) to “dark to bright” (db) for $O_1$ and $O_3$, we get different results for the same input image with the expected global properties, demonstrating that our algorithm is working correctly, as depicted in the slice views and 3D renderings of the objects in Figures 4.10 and 4.11.

![Diagram](image)

**Figure 4.10:** (a) Given the input image with six regions and seeds for $O_1$ (in yellow), $O_2$ (in blue) and background (in red), we obtain the result for $O_1$ and $O_2$ included in $O_3$, where $O_1$ has boundary polarity from bright to dark and $O_2$ from dark to bright. In (b) a slice view is shown and in (c) the 3D renderings of the objects.

In order to test our 3D HLOIFT in a real MR image, we reduced the image size by interpolation to $120 \times 120 \times 90 = 1296000$ voxels. We segmented the brain (Figure 4.12a) and the lateral ventricles (Figure 4.12b) using the inclusion relation. The running time was 4.2 sec in a laptop IntelCore i3-5005U CPU 2.00GHz.

The main challenges correspond to the required space and execution time, since in multidimensional data the memory consumption grows exponentially with the increase in the number of dimensions. Here we present the results of applying HLOIFT to 3D volumes, through the direct application of its proposed algorithm, without taking any additional precautions to get a more moderate usage of memory, in order to test its viability in this more
Figure 4.11: (a) Given the input image with six regions and seeds for $O_1$ (in yellow), $O_2$ (in blue) and background (in red), we obtain the result for $O_1$ and $O_2$ included in $O_3$, where $O_1$ and $O_2$ have boundary polarity from dark to bright, and $O_3$ has the opposite orientation from bright to dark. In (b) a slice view is shown and in (c) the 3D renderings of the objects.

Figure 4.12: Example of 3D HLOIFT segmentation in a real MR image. (a) The brain. (b) The lateral ventricles.

challenging scenario. One possible idea, as future work, would be to avoid the explicit creation of the inter-layer arcs, since they have repeated weights $-\infty$ or $\infty$. When the intra-layer weights of different layers differ only in relation to their values of $\alpha_i$, the base dissimilarity values $\psi(s,t)$ could be stored only once, being the orientation procedure of Equation 2.3 applied on-the-fly to save storage space. Another alternative solution is via the usage of supervoxels, since they considerably reduce the execution time as it will be demonstrated for superpixels in next section.
4.3 Experimental evaluation with superpixels

This section presents an experimental evaluation of the usage of superpixels in HLOIFT to assess its performance gains. In our first experiment, presented in Table 4.2, we show the execution time gains of the proposed approach in comparison to Image Foresting Transform (IFT) (Miranda e Falcão, 2009) and the multiple object segmentation by the regular HLOIFT (Leon et al.) without superpixels, for different image resolutions and superpixel sizes, for the segmentation of three objects in a CT image of the knee with inclusion and exclusion relations. The usage of superpixels in HLOIFT significantly reduced the size of the graph, resulting in a great saving of memory and computation time, thus compensating the additional cost of the three object-digraphs (layers) of HLOIFT in relation to IFT that has a single layer. Moreover, the segmentation results for different superpixel sizes were similar to those obtained by HLOIFT at the pixel level demonstrating the robustness of the proposed method (Figure 4.13).

Table 4.2: Time in ms for the different methods and image resolutions.

We also compared the running time between our approach and the hierarchical min-cut/max-flow algorithm with the inclusion case from Delong e Boykov (2009). Our approach has the best running time. For the flower segmentation from Figure 4.7, composed of two objects with the inclusion relation and size of $1520 \times 1280$ pixels, our algorithm takes 158.35 ms, 58.06 ms and 20.38 ms for superpixels of size $3 \times 3$, $5 \times 5$ and $10 \times 10$, respectively, while the regular HLOIFT takes 1,823.55 ms and the hierarchical min-cut/max-flow takes 19,021.71 ms. All experiments presented in this section were conducted in a laptop Intel Core i3-5005U CPU 2.00GHz ×4.

5.1 Final considerations

We proposed a new graph-based algorithm, named as HLOIFT, for multi-object segmentation, allowing the integration of the individual high-level priors of each object and the geometric constraints between them into a single energy optimization. The HLOIFT algorithm was described in details, including its proof of correctness. Besides the theoretical contribution in the context of the multi-object segmentation problem, our experiments show that good segmentation results can be obtained, even when considering a simple measure of intensity dissimilarity. Besides being faster than hierarchical min-cut/max-flow based approaches, it is also less restrictive, allowing globally optimal results for arbitrary hierarchies.

Finally, we presented how the HLOIFT method can be easily extended to work with 3D images. However, we note that under this last scenario, the usage of supervoxels can play an important role to circumvent memory concerns in machines with limited memory resources. Therefore, we also proposed a superpixel-based adaptation of the HLOIFT method, leading to a more efficient and adequate solution for multi-object segmentation in large images.

5.2 Publications

As results of this thesis, we have one conference publication, one submitted journal, one workshop publication in a book and three workshop poster presentations. These contributions are listed below in chronological order of submission:

1. A conference paper (Leon e Miranda, 2017), in the 30th SIBGRAPI Conference on Graphics, Patterns and Images (SIBGRAPI) held in Niterói, Rio de Janeiro. Qualis CAPES B1. Oral presentation. This paper was selected as one of the top papers of the event and we were invited to submit an extended version to a journal.

2. Submission of a journal paper (Leon et al.) at the special issue of the Journal of Visual Communication and Image Representation: Special Issue on Feature representations.
for medical images and activity understanding. Qualis CAPES A2. This extended version was made in cooperation with Krzysztof Chris Ciesielski from Department of Mathematics, West Virginia University, USA.

3. A book chapter (Leon e de Miranda, 2019), from the workshop of Women in Computer Vision at European Conference in Computer Vision (WiCV@ECCV) held in Munich, Germany. Published in the ECCV Workshop proceedings. Poster presentation.

4. A workshop poster (Leon e Miranda, 2018), in the Latinx in AI Coalition at NeurIPS (LXAI@NeurIPS) held in Montréal, Canada. Poster presentation.

5. A workshop poster (Leon et al., 2019b) in the Women in Computer Vision at CVPR (WiCV@CVPR), and a workshop poster (Leon et al., 2019a) in the Latinx in AI Coalition at ICML (LXAI@ICML), both held in Long Beach, United States. Poster presentation.

5.3 Future works

As future work, we are interested in:

1. To study and test other high-level priors such as connectivity priors, and spatial interactions between objects, like their relative spatial positioning (up, down, left, right);

2. To evaluate our 3D image segmentation, also considering different high-level priors, in open databases like 3D-IRCADb-02 (Soler et al., 2012), which contains axial cross sections of CT thoracic-abdominal images (see Figure 5.1).

Figure 5.1: Example of a thoracic-abdominal image from 3D-IRCADb-02 dataset (Soler et al., 2012).
3. We would like also to handle relations of partial intersection of objects, as shown in Figure 5.2, by using a negative parameter $\rho$;

![Figure 5.2](image.png)

**Figure 5.2:** Example of cells with overlapping regions. *In the left we have the input image, and in the right a desired segmentation.*

4. We are interested in using a machine learning method to generate improved weighted graphs and to adapt our method for an automatic medical image segmentation task.

5. We also intend to combine some training information by deep learning approaches in HLOIFT, similar to what was done in Wolf *et al.* (2017); Wolf *et al.* (2019), and to incorporate in HLOIFT the relaxation procedure for directed graphs from Demario e Miranda (2019), in order to circumvent the irregular boundaries from the max-norm energy of HLOIFT.
A.1 Proof of Theorem 1

Since the digraph \( \mathcal{H} \) is built from an image, it is symmetric and connected. So, it is easy to see that upon its termination HLOIFT returns \( X \) defined on the entire set \( \mathcal{N} \). Therefore, to finish the proof, we need only to show that such \( X \) satisfies the seed constrains and the consistency requirements (C).

All notions considered below are based on the variables from Algorithm 3. In particular, the values of these variables may change during the execution of the algorithm.

Define \( D = \{ t \in \mathcal{N}: S(t) = 1 \} \). Then, at any time, the partial binary map \( X \) is already defined on \( D \) and, for every \( t \in D \), the value of \( X(t) \) remains unchanged during the reminder of the execution of the algorithm. (Such change can occur only during the execution of lines 14 or 17, and it can be applied only for \( t \) for which, in line 10, we had \( S(t) = 0 \), that is, \( t \notin D \).)

Notice also that if \( t \) in \( Q \) is not a seed, then there exists an \( s \in D \) such that \( (s, t) \in A \), \( X(t) = X(s) \), and \( V(t) = w_{X(s)}(s, t) \), where we use notation \( w_i \) from Remark 1. In addition, the value \( V(t) \) represents a “penalty” (i.e., a contribution to the final energy \( \varepsilon_{\text{h}}^\text{min} \) cost) of a potential change of the value \( X(t) \) from its current value \( X(s) \) to \( 1 - X(s) \).

Directly after the execution of the initialization loop 1-6, the queue \( Q \) will consists precisely of the nodes from the set \( \mathcal{S} = \{ \langle s, i \rangle: i \in \mathcal{L} \& s \in \mathcal{S}_i \} \), that is, seed representations in the HLOIFT graph \( \mathcal{N} \). Let \( X_0 \) denote the map \( X \) defined on \( \mathcal{S} \) at this time. Since, at this time, we also have \( X(t) = -\infty \) for every \( t \in \mathcal{S} \), these values cannot ever be changed, as the condition in line 13 is never satisfied. Also, for any \( X: \mathcal{N} \to \{0, 1\} \),

\[
X \text{ satisfies the seed constrains if, and only if, } X \text{ extends } X_0.
\]

In particular, any \( X: \mathcal{N} \to \{0, 1\} \) returned by HLOIFT has this property. Therefore, to finish the proof, it is enough to show that such \( X \) also satisfies the consistency requirements (C).

By consistency of \( \mathcal{S} \) with (C), the family \( \mathcal{X} \) of all \( X: \mathcal{N} \to \{0, 1\} \) satisfying the seed constraints and the consistency requirement (C) is non-empty. In particular, any \( X \in \mathcal{X} \) extends...
$X_0$ and has energy $\varepsilon^h_{\min}(X) > -\infty$ (as, by the choice of inter-layer weights, $\varepsilon^h_{\min}(X) = -\infty$ only when $X$ fails the consistency requirement (C)). Let $E$ be the maximum of $\varepsilon^h_{\min}(X)$ over all $X \in \mathcal{X}$ and let $X_0$ be the family of all $X \in \mathcal{X}$ with $\varepsilon^h_{\min}(X) = E$. Notice that $E > -\infty$.

The two key steps of our proof are the following closely related versions of preservation properties (P) and (Q). The above discussion shows that the assumptions of both of these properties are satisfied directly after the execution of the initialization loop.

The property (P) reads as follows.

(P) Assume that, directly before an execution of the line 8, the current $X$ (defined on a $D \subset \mathcal{N}$) is a restriction of an $\bar{X} \in X_0$. If, during the following execution of line 8, we remove $t$ from $Q$ with $V(t) < E$, then the extension of $X$ to $D \cup \{t\}$ also agrees with $\bar{X}$, that is, $X(t) = \bar{X}(t)$.

Indeed, if $t \in \mathcal{S}$, then, as we argued above, $\bar{X}(t) = X_0(t) = X(t)$. Otherwise, there is an $s \in D$ such that $(s, t) \in \mathcal{A}$ and the current values of $V(t)$ and $X(t)$ were fixed during the execution of lines 8-17, when our node $s$ was removed from $Q$. This means that we could not have simultaneously $(s, t) \in \mathcal{A}_s$ and $X(s) = 0$.

If $(s, t) \in \mathcal{A}_s$ and $X(s) = 1$, then, during the execution of line 17, we have set $X(t) = 0$. At the same time, we must have $\bar{X}(t) = 0$, since otherwise we would have $\bar{X}(t) = 1 = X(s) = \bar{X}(s)$, making $\varepsilon^h_{\min}(\bar{X}) = \varepsilon^{\text{excl}}_{\min}(\bar{X}) = -\infty \neq E$, a contradiction. So, indeed, $X(t) = 0 = \bar{X}(t)$.

To finish the argument for (P) we can assume that $(s, t) \notin \mathcal{A}_s$. Then, the executions of lines 8-17 ensures that $X(t) = X(s)$. At the same time we must have that $\bar{X}(s) = \bar{X}(t)$, as otherwise

$$ E = \varepsilon^h_{\min}(\bar{X}) \leq \varepsilon^{\text{incl}}_{\min}(\bar{X}) \leq w_{X(s)}(s, t) = w_{X(s)}(s, t) = V(t) < E, $$

impossibility.

Therefore, indeed $X(t) = X(s) = \bar{X}(s) = \bar{X}(t)$, finishing the argument for (P).

The second preservation property is as follows.

(Q) Assume that, directly before an execution of the line 8, the current $X$ (defined on a $D \subset \mathcal{N}$) can be extended to an $\bar{X} \in X_0$. If, during the following execution of line 8, we remove $t$ from $Q$ with $V(t) \geq E$, then the extension $X$ to $D \cup \{t\}$ has a further extension to an $\hat{X} \in X_0$. We have $V(t) > -\infty$, as $V(t) \geq E > -\infty$. For the main part of the argument for (Q) assume that we also have $V(t) < \infty$.

As $V(t)$ is finite, there must exist an $s \in D$ such that $(s, t) \in \mathcal{A}$ is an intra-arc and the current values of $V(t)$ and $X(t)$ were fixed during the execution of lines 8-17, when our node $s$ was removed from $Q$. We need to show that the extension $X$ to $D \cup \{t\}$ has a further extension to an $\hat{X} \in X_0$. For $i \in \{0, 1\}$ let $R_i = \{d \in D : X(d) = i\}$. 

If $X(t) = 0$, then the indicator (i.e., characteristic) function $\chi_{R_1}$ is the desired $\hat{X} \in \mathcal{X}_0$ extending $X$. Indeed, it certainly extends $X$ (which, in turn, extends $X_0$) and has an energy $\varepsilon^h_{\min}(\hat{X}) = \min\{\varepsilon^{\text{incl}}_{\min}(\hat{X}), \varepsilon^{\text{excl}}_{\min}(\hat{X})\} \geq E > -\infty$, where the equation is justified by $\varepsilon^{\text{excl}}_{\min}(\hat{X}) = \varepsilon^h_{\min}(\hat{X})$ (which holds, as we have $\{s \in \mathcal{N}: \hat{X}(s) = 1\} = \{s \in \mathcal{N}: \hat{X}(s) = 1\}$) while the inequality $\geq$ by $\varepsilon^{\text{incl}}_{\min}(\hat{X}) \geq \min\{V(s): s \in Q\} \geq V(t) \geq E$ and $\varepsilon^{\text{excl}}_{\min}(\hat{X}) \geq \varepsilon^h_{\min}(\hat{X}) = E$. Hence, $\hat{X} \in \mathcal{X}_0$.

So, assume that $X(t) = 1$ and notice that $(s,t) \notin \mathcal{A}_i$; for $X(s) = 0$ this is ensured by line 13, while for $X(s) = 1$ by line 16. In particular, we also have $X(s) = 1$. A first impulse could be to define $\hat{X}$ as the indicator $\chi_{\mathcal{N}\setminus R_0}$. However, $\varepsilon^h_{\min}(\chi_{\mathcal{N}\setminus R_0}) \leq \varepsilon^{\text{excl}}_{\min}(\chi_{\mathcal{N}\setminus R_0})$ and it is likely that $\varepsilon^{\text{incl}}_{\min}(\chi_{\mathcal{N}\setminus R_0}) = -\infty$. So, in this case, $\hat{X}$ needs to be defined more carefully. Specifically, let $i = \lambda(t)$ and let $\mathcal{L}'$ be the set of all ancestors of $i$; all $j \in \mathcal{L}$ such that, according to $h$, $O_i \subset O_j$. Let

$$R = R_1 \cup \{t \in \mathcal{N} \setminus R_0: \lambda(t) \in \mathcal{L}'\}$$

and put $\hat{X} = \chi_R$. Then, $\hat{X}$ extends $X$ which, in turn, extends $X_0$. So, $\hat{X}$ satisfies seeds constrains and, to show that $\hat{X} \in \mathcal{X}_0$, it is enough to prove that $\varepsilon^h_{\min}(\hat{X}) > -\infty$.

To see this, first notice that $\varepsilon^{\text{excl}}_{\min}(\hat{X}) = \infty$. Indeed, otherwise there would exist $u,v \in R$ with $(u,v) \in \mathcal{A}_s$ and $\hat{X}(u) = \hat{X}(v) = 1$. However, they cannot both belong to $R_1$, since this would mean that $E = \varepsilon^h_{\min}(\hat{X}) = -\infty$. They cannot both belong to $R \setminus R_1$, since $\mathcal{L}'$ contains no siblings. Finally if one of these nodes belongs to $R_1$, say $u \in R_1$, then the other cannot be in $R \setminus R_1$. Indeed, this would mean that $u \in D$ and at the time when $u$ was removed from $Q$, the value $V(v) = -\infty$ was assigned. This $V(v) = -\infty$ cannot be ever increased during execution of HLOIFT. With $v \in Q$, this contradicts the minimality $V(t) \geq E$, as $E > -\infty = V(v)$. So, indeed, $\varepsilon^h_{\min}(\hat{X}) = \infty$.

From this, $\varepsilon^h_{\min}(\hat{X}) = \min\{\varepsilon^{\text{incl}}_{\min}(\hat{X}), \varepsilon^{\text{excl}}_{\min}(\hat{X})\} \geq E > -\infty$, where the equation is justified by $\varepsilon^{\text{incl}}_{\min}(\hat{X}) = \infty = \varepsilon^{\text{excl}}_{\min}(\hat{X})$, while the inequality $\geq$ by the facts that $\varepsilon^{\text{incl}}_{\min}(\hat{X}) \geq \min\{V(s): s \in Q\} = E$ and $\varepsilon^{\text{excl}}_{\min}(\hat{X}) \geq \varepsilon^h_{\min}(\hat{X}) = E$. This completes the proof of $(Q)$ in case $V(t) < \infty$.

To finish the proof of $(Q)$ it is enough to show that $V(t) = \infty$ is impossible. Indeed, the consistency of the seeds ensures that either $\lambda(t)$ or some of its descendants, say $j$, contains a seed, say $u$. In particular, $s_0 = \langle j, u \rangle \in D$ and $X(s_0) = X_0(s_0) = 1$. Also, $\mathcal{H}$ contains a path from $s_0$ to $s = \langle \lambda(t), u \rangle$ with each connecting arc having weight $-\infty$. Therefore, $s$ must belong to $D$, as otherwise we would have $E = -\infty$. Since $s \in \mathcal{N}_\lambda(t)$ and $\mathcal{N}_\lambda(t)$ is connected and symmetric, it contains adjacent $u$ and $v$ with $u \in D$ and $v \in Q$. Hence, $V(t) \leq V(v) < \infty$, finishing the proof of $(Q)$.
